Abstract: Dinosaurs were ubiquitous in terrestrial ecosystems through most of the Mesozoic and are still diversely represented in the modern fauna in the form of birds. Recent efforts to better understand the origins of the group have resulted in the discovery of many new species of early dinosaur and their closest relatives (dinosauromorphs). In addition, recent re-examinations of early dinosaur phylogeny have highlighted uncertainties regarding the interrelationships of the main dinosaur lineages (Sauropodomorpha, Theropoda and Ornithischia), and questioned the traditional hypothesis that the group originated in South Gondwana and gradually dispersed over Pangaea. Here, we use an historical approach to examine the impact of new fossil discoveries and changing phylogenetic hypotheses on biogeographical scenarios for dinosaur origins over 20 years of research time, and analyse the results in the light of different fossil record sampling regimes. Our results consistently optimize South Gondwana as the ancestral area for Dinosauria, as well as for more inclusive clades including Dinosauromorpha, and show that this hypothesis is robust to increased taxonomic and geographic sampling and divergent phylogenetic results. Our results do not find any support for the recently proposed Laurasian origin of dinosaurs and suggest that a southern Gondwanan origin is by far the most plausible given our current knowledge of the diversity of early dinosaurs and non-dinosaurian dinosauromorphs.

Key words: Dinosauria, sampling, biogeography, BioGEOBEARS, Triassic, Gondwana.

Dinosaurs dominated Mesozoic terrestrial ecosystems for more than 140 million years, and remain highly diverse today, in the form of birds. As such, dinosaurs represent an outstanding example of evolutionary success among terrestrial tetrapods, which is reflected by the broad scientific interest in the group. Recently, there has been intense debate over the origins, early evolutionary radiation, and rise to ecological dominance of the group, stimulated by new discoveries of early dinosaurs and closely related taxa (Irmis et al. 2007; Nesbitt et al. 2009, 2010, 2013, 2017; Cabreira et al. 2011, 2016; Martínez et al. 2011), novel quantitative macroevolutionary analyses (Brusatte et al. 2008a, b; Sookias et al. 2012; Benton et al. 2014) and new geological data (Whiteside et al. 2015; Marsicano et al. 2016; Bernardi et al. 2018; Langer et al. 2018).

The discovery of many of the earliest known fossils of dinosaurs and their close relatives, non-dinosaurian dinosauromorphs, in South America and other southern portions of the supercontinent Pangaea has led to the hypothesis that dinosaurs originated in this region (Nesbitt et al. 2009; Brusatte et al. 2010; Langer et al. 2010). However, a recent high-profile reassessment of the early dinosaur evolutionary tree (Baron et al. 2017a) not only challenged the long-standing classification of the three main dinosaur lineages (Seeley 1887; Gauthier 1986) but also questioned the southern Gondwanan origin of the clade. Based solely on the observed paleogeographical distribution of some of the closest relatives of Dinosauria in their phylogenetic hypothesis (i.e. the Late Triassic Saltopus elginensis and the Middle–Late Triassic Silesauridae, which were recovered in a polytomy with Dinosauria), Baron et al. (2017a, b) proposed that dinosaurs may have originated in the northern part of Pangaea, referred to as Laurasia. However, this was suggested in the absence of any formal biogeographical analysis. Langer et al. (2017)
tested this hypothesis by running several quantitative biogeographical analyses to reconstruct ancestral areas, the results of which consistently recovered a southern Pangaean (or Gondwanan) origin for dinosaurs. However, they only conducted these analyses for the Baron et al. (2017a) topology and did not consider alternative phylogenetic scenarios (Cabreira et al. 2016), or the long-term robustness of these results to new fossil discoveries.

In this paper we aim to: (1) further test hypotheses about the ancestral distribution of dinosaurs using a broader range of quantitative biogeographical models and alternative phylogenetic hypotheses; (2) test the stability of the biogeographical results over 20 years of additional scientific discoveries and new research that have dramatically changed our understanding of early dinosaur evolution; and (3) discuss how biased palaeogeographical sampling of the fossil record might impact our scenarios for dinosaur origins.

MATERIAL AND METHOD

Source trees and time scaling

We sampled trees from six independent phylogenetic analyses from the last 20 years, each of which dealt with the major diversity of early dinosauromorphs at the time they were published: (1) Sereno (1999); (2) Langer & Benton (2006); (3) Nesbitt et al. (2009); (4) Cabreira et al. (2016); (5) Baron et al. (2017a); and (6) Langer et al. (2017) (Fig. 1). For the Baron et al. (2017a) dataset, we created three alternative topologies to explore the impact of the uncertain relationships between Saltopus, Silesauridae and Dinosauria found by that study. The three topologies differ in the following arrangements: A, Saltopus sister to Silesauridae + Dinosauria; B, Saltopus sister to Silesauridae; and C, Saltopus sister to Dinosauria. We pruned Cretaceous taxa from the chosen topologies, as their biogeographical range is beyond the scope of our study. Supraspecific taxa were replaced by specific representatives of the same clade in order to generate a more explicit geographical distribution of terminal nodes. For example, in the topology of Sereno (1999) we replaced Diplodocidae with Diplodocus.

Since the biogeographical methods employed here require fully-solved, time-calibrated topologies, we resolved all polytomies in the sampled trees according to the following procedure. For hypotheses resulting from many most parsimonious trees (MPTs; Langer et al. 2017), we first obtained a majority-rule consensus tree (cut-off = 50). The remaining polytomies were manually resolved using a standardized procedure suggested by previous studies (Upchurch et al. 2015; Ferreira et al. 2018). First, wherever possible we resolved polytomies to minimize biogeographical changes. For example, in a polytomy (A, B, C) where A and B share the same range, but C has a different range, we resolved A + B as sister-taxon to the exclusion of C. We further resolved polytomies based on relationships recovered in previous analyses. Finally, if polytomies remained, we chose the arrangement by randomly selecting one of the possible MPTs of that analysis. The dichotomous trees were then time-scaled using the R package *strap* (Bell & Lloyd, 2014), with branch lengths equally divided (Brusatte et al. 2008b) and a minimum branch length of 1 myr. Time ranges were based on the oldest and earliest dates of the stratigraphic stage (according to the International Chronostratigraphic Chart v. 2017/02; Cohen et al. 2013) in which a taxon occurs, the latter data being gathered from the literature. For example, the first and last appearances of all Carnian taxa were considered to be 237 and 227 Ma, respectively.

Biogeographical analyses

In order to investigate the influence of phylogenetic uncertainty and sampling on ancestral distribution estimates for dinosaurs we conducted a series of stratified biogeographical analyses with the R package *BioGeoBEARS* (Matzke 2013) using the aforementioned phylogenetic trees. For each analysis, we ran two nested-models (M0 and M1; see below) of the likelihood-based models DEC (Dispersal-Extinction Cladogenesis; Ree 2005; Ree & Smith 2008) and DIVALIKE (Dispersal-Vicariance Analysis; Ronquist 1997). The DEC+J model was not explored because of its conceptual problems (Ree & Sanmartin 2018). Even though *BioGeoBEARS* enables us to fit a large number of additional models by changing the available parameters, for example the implemented likelihood version of BayArea (Landis et al. 2013), we opted to employ only the most commonly used biogeographical models, DEC and DIVA, to reduce the total number of analyses, since we are testing several sets of analyses based on different phylogenetic hypotheses. Each taxon was scored for four biogeographical provinces as defined by Langer et al. (2014): South Gondwana (S), Equatorial Belt (B), Euramerica (A), and Trans-Uralian domains (T). We set a maximum range size of two areas. Even though our analyses are temporally restricted to between the Middle Triassic and Middle Jurassic, a period during which no drastic palaeobiogeographical changes between the considered areas are supposed to have occurred, we conducted time-stratified analyses dividing the trees into two discrete periods: Middle Triassic to Norian (247.2–208.6 Ma) and Rhaetian to Middle Jurassic (208.5 Ma to the earliest tip of each tree). For each time stratum, a dispersal multiplier matrix was specified to model the
arrangement between the defined areas. To compare the effects of these assumptions, we followed the procedure of Poropat et al. (2016) and conducted analyses with ‘harsh’ and ‘relaxed’ versions of the ‘starting’ dispersal multiplier matrices (Marsola et al. 2018, appendix S1), and also set the parameter $w$ to be free in one of the models (M1; for M0 $w$ is set to 1) in order to infer optimal dispersal multipliers during the analyses. It is important to consider that distinct models (e.g. DEC and DIVA) make specific assumptions about the biogeographical processes of range change. For that reason, the maximum-likelihood approach of BioGeoBEARS allowed us to test and choose the best fit model (Matzke 2014), using the likelihood-ratio test (LRT) and the weighted Akaike information criterion (AICc).

RESULTS

With the sole exception of the ‘starting’ analysis of the Langer & Benton (2006) tree, for which a joint distribution of South Gondwana and Euramerica was estimated for the Dinosauria node, the best fit models (for LRT and AICc test results see Marsola et al. 2018) obtained from all our analyses support a strictly southern Gondwanan origin for dinosaurs (Table 1). Changing the dispersal multiplier matrices did not yield distinct estimates. Similarly, our results yield high support for South Gondwana as the ancestral area for other ornithodiran clades leading to the Dinosauria node. Whereas all analyses of the Nesbitt et al. (2009) dataset and the ‘starting’ version of the Langer & Benton (2006) dataset support a joint distribution of South Gondwana and Euramerica as the ancestral area for Dinosauromormorphs, the clades Dinosauromormorphs and Dinosauriformes are supported as originating in South Gondwana in all other analyses, including those datasets that have the most extensive sampling of non-dinosaurian dinosauromorphs (Cabreira et al. 2016; Baron et al. 2017a; Langer et al. 2017). South Gondwana is also inferred as the ancestral area for the Silesauridae + Dinosauria clade in all analyses in which this sister-group relationship is present (i.e. not in Sereno (1999) or iteration C of the Baron et al. (2017a) dataset) with the exception of the ‘harsh’ analysis of the Langer &

All results are available in Marsola et al. (2018, appendix S1).

Benton (2006) dataset. We note that the results for the Langer & Benton (2006) tree may not be reliable due to the low taxon sampling of the tree and the short branches surrounding Dinosauria.

Our results do not therefore support the hypothesis of a Laurasian origin for Dinosauria as proposed by Baron et al. (2017a), regardless of which of their three alternative topologies (Baron et al. (2017a): trees A, B and C) is employed. Although the problematic taxon Saltopus elgi-nensis is known from Laurasia (Lossiemouth Sandstone Formation of Scotland, generally considered to be late Carnian in age, and almost certainly Late Triassic; Benton & Walker 2011), it is phylogenetically nested among South Gondwanan taxa in all alternative hypotheses and occurs stratigraphically 10–15 million years later than the main splitting events along the dinosauromorph lineage leading up to the origin of dinosaurs. Likewise, although Baron et al. (2017a) noted that the Laurasian Agnosphitys cromhallensis was positioned as sister to other silesaurids in their results, this taxon is known from the Rhaetian fissure fill deposits of southwest England, that is some 35–40 million years after the inferred origin of Silesauridae. All known Middle Triassic non-dinosaurian dinosauromorphs, as well as the only putative Middle Triassic dinosaur (Nesbitt et al. 2013), are from South Gondwana and only from the Carnian onwards does their range expand into the northern hemisphere.

We conclude therefore, that the phylogenetic hypothesis proposed by Baron et al. (2017a) does not provide any significant support for a Laurasian origin of dinosaurs (Fig. 2). Instead, all our results strongly support those of Nesbitt et al. (2009) and Langer et al. (2017) (Figs 2, 3), in which southern Gondwana (‘southern Pangaea’ and ‘South America’, respectively, in their own terms) was also recovered as the ancestral area for dinosaurs. Furthermore, our analyses show that Ornithoscelida and Saurischia would also have originated in southern Gondwana in all possible versions of the Baron et al. (2017a) phylogenetic hypothesis.

**DISCUSSION**

**Historical patterns**

Palaeontologists frequently use ancestral-area reconstruction approaches, such as those implemented by BioGeo-BEARS, to infer ancestral ranges for clades and use these to make inferences about evolutionary histories (Upchurch et al. 2015; Poropat et al. 2016; Ferreira et al. 2018). However, they much more seldomly consider the robustness of those results to new fossil discoveries, which may include taxa from previously unsampled areas, and changes in phylogenetic hypotheses, which occur through the addition of more taxa and/or through changing topologies that result from new datasets or analytical approaches. For an ancestral range hypothesis to be considered well supported, it should be robust to such changes in the source data.

Here, we have provided a unique historical perspective on early dinosaur biogeography, by reconstructing ancestral areas for a series of alternative phylogenetic topologies taken from the last 20 years of research effort. Our key result, a South Gondwana origin for dinosaurs, has proved remarkably stable over two decades of new fossil discoveries and extensive phylogenetic research. Since the work of Sereno (1999), 23 new Triassic dinosaurs and non-dinosaurian dinosauromorphs have been discovered and/or added to phylogenetic studies. This includes new taxa from North America (Irmis et al. 2007; Nesbitt et al. 2009; Sues et al. 2011), Europe (Fraser et al. 2002; Dzik, 2003; Benton & Walker 2011) and North Africa (Kammerer et al. 2012). Yet, this greatly increased sampling has had few major impacts on models of early dinosaur biogeography, as the southern Gondwanan origin for the group is invariably supported as the best model throughout the research interval considered. We recommend using a similar historical perspective when estimating
ancestral distributions of other clades, as a way of examining the support for biogeographical hypotheses.

Our results are also consistent despite highly divergent phylogenetic hypotheses for early dinosaurs. For example, Cabreira et al. (2016) recovered the majority of silesaurids within Dinosauria, as a paraphyletic array of early ornithischians. Baron et al. (2017a, b) proposed the unconventional clade Ornithoscelida, with Ornithischia as the sister-taxon of Theropoda, and herrerasaurids nested with sauropodomorphs within Saurischia, whereas Langer et al. (2017) reiterated support for a traditional Ornithischia–Saurischia dichotomy at the base of Dinosauria. However, our results show that none of these conflicting rearrangements of the three main dinosaurian lineages (Sauropodomorpha, Theropoda, Ornithischia) and Silesauridae challenge the long-standing biogeographical hypothesis of a southern Gondwanan origin for dinosaurs.

**Sampling biases**

A biogeographical hypothesis, such as the southern Gondwanan origin of Dinosauria, may be well supported through research time and under alternative phylogenetic topologies, but could still be flawed if fossil record sampling is highly heterogeneous. For example, if dinosaurs actually originated in the late Middle to earliest Late Triassic in Laurasia, and dispersed quickly across the globe, they might still be reconstructed as ancestrally from South Gondwana if that region is the only one from which terrestrial vertebrate fossils have been sampled in that time interval. Reconstructions of ancestral areas for fossil taxa should therefore always be considered within an explicit consideration of how the fossil record has been sampled spatially, and temporally, but this is rarely the case. Here, we briefly discuss fossil record sampling through the inferred origin and initial radiation of dinosaurs (Middle
Triassic to early Late Triassic: Anisian–Carnian), and the implications for the South Gondwana origins hypothesis.

The earliest dinosauromorph body fossils, as well as the oldest putative dinosaur body fossil, are known from the Middle to earliest Late Triassic of South Gondwana, most notably from the Manda Beds of Tanzania (Nesbitt et al. 2010, 2013, 2017) and the Chañares Formation of Argentina (Sereno & Arcucci 1994a, b; Bittencourt et al. 2015; Ezcurra et al. 2017; Fig. 4). These represent two of the best-sampled stratigraphic units for terrestrial tetrapods in this interval, but Laurasian tetrapods of broadly comparable stratigraphic ages are known from various Laurasian localities, including the USA (Moenkopi Formation; Nesbitt 2005), the UK (Helsby Sandstone Formation; Coram et al. in press), Russia (Donguz and Bukobay gorizons; Gower & Sennikov 2000), Germany (Erfurt Formation; Schoch & Sues 2015) and China (Ermaying Formation; Sookias et al. 2014). To date, none of these Laurasian deposits have yielded dinosauromorph body fossils (Fig. 4).

Similarly, the earliest definitive dinosaur body fossils are from the early Late Triassic (late Carnian) of Argentina and Brazil (Alcober & Martínez 2010; Brusatte et al. 2010; Ezcurra 2010; Langer et al. 2010; Cabreira et al. 2011, 2016; Martínez et al. 2011; Müller et al. 2018; Pretto et al. 2018) (Fig. 4). Although the dating of many Laurasian rock sequences of putatively similar age is controversial, those in Germany (Butler et al. 2014), Poland (Dzik & Sulej 2007), North America (Sues & Olsen 2015) and the UK (Benton & Walker 1985) have failed thus far to yield definite dinosaur remains, although the silesaurid *Silesaurus* is known from Poland (Dzik 2003), and the problematic *Saltopus* from the UK (Benton & Walker 2011).

Putative dinosauromorph footprint records have been reported from the Early–Middle Triassic of Laurasia (Brusatte et al. 2011). These include the ichnogenus *Prorotodactylus* from the Olenekian of Poland (Brusatte et al. 2011; Niedźwiedzki et al. 2013) and the ichnogenus *Rotodactylus* from the late Olenekian to Ladinian of Poland,
Germany, France, the UK and the USA (Peabody 1948; Haubold 1999; Brusatte et al. 2011; Tresise & King 2012; Niedzwiedzki et al. 2013). If this interpretation of trackmaker affinities is correct, it represents a significant challenge to our current understanding of the biogeography of early dinosauromorphs (although not necessarily dinosaurs) suggesting that they were widespread over northern Pangaea in the late Early to Middle Triassic. However, trackmaker affinities for footprint ichnogenera are often difficult to constrain, and other workers have challenged the identification of Prorotodactylus and Rotodactylus as dinosauromorphs (Padian 2013), suggesting that they could instead represent basal archosauromorph or lepidosauromorph trackways.

In order to test the effects of the possible dinosauromorph affinities of the above-mentioned ichnogenera for dinosauromorph and dinosaur biogeography, we performed sensitivity analyses with Prorotodactylus added to the Baron et al. (2017a: tree C) and Langer et al. (2017) datasets (see Marsola et al. 2018). To do this, we considered two alternative possible scenarios where Prorotodactylus is sister-taxon to all other dinosauromorphs or is sister-taxon to all lagerpetids. Invariably, the results (Marsola et al. 2018, appendix S1) consistently continue to infer South Gondwana as the ancestral area for both Dinosauria and Dinosauriformes. On the other hand, a joint distribution of South Gondwana and Euramerica as the ancestral area for Dinosauria is supported in most cases, although some analyses also suggest a joint distribution of Equatorial Belt and Euramerica.

It remains possible that, as suggested by Baron et al. (2017b), better future sampling of Middle to early Late Triassic localities from Laurasia will overturn the South Gondwana hypothesis for dinosaur origins. However, compared to those from South Gondwana, these areas have been much more extensively sampled by palaeontologists for over 150 years and have so far failed to yield body fossils of Middle Triassic dinosauromorphs or early Late Triassic dinosaurs.

CONCLUSIONS

The last two decades have witnessed a great increase in the taxonomic sampling of Triassic dinosaurs and non-dinosaurian dinosauromorphs. Unearthed from different parts of the world, these new discoveries have helped palaeontologists to better understand not only the morphology and diversity of early dinosaurs, but also to develop new models for their rise. Along with these new finds, new phylogenetic hypotheses for early dinosaurs have been proposed. These have challenged conventional understanding of the relationships of the main dinosaurian lineages (Cabreira et al. 2016; Baron et al. 2017a; Langer et al. 2017) and questioned the long-standing hypothesis of a southern Gondwanan origin for the clade (Baron et al. 2017a; Langer et al. 2017). In this study, we have shown that even in the most divergent phylogenetic hypotheses of early dinosaurs, a southern Gondwanan origin is strongly supported by quantitative biogeographical analyses. Additionally, we have demonstrated that South Gondwana is consistently supported as the ancestral area in a range of phylogenies from the last 20 years, and has therefore been robust to increases in taxonomic, geographical and phylogenetic
sampling. Although Middle–Late Triassic rock sequences worldwide have been sampled for decades, the oldest unequivocal dinosaur body fossil remains are still clustered in southern Gondwanan deposits. Given the present data, the South Gondwana hypothesis must therefore be considered the best-supported interpretation of the ancestral area for the rise of dinosaurs.

Author contributions. RJB conceived the study. JCAM collected data. JCAM, GSF, and DJB conducted analyses. JCAM, GSF and RJB wrote the paper. All authors revised and contributed comments to the final manuscript.
